Abstract

The history of DNA sequencing dates back to 1970s. During this period, the two first-generation nucleotide sequencing techniques were developed. Subsequently, Sanger's dideoxy method of sequencing gained popularity over Maxam and Gilbert's chemical method of sequencing. However, in the last decade, we have observed revolutionary changes in DNA sequencing technologies leading to the emergence of next-generation sequencing (NGS) techniques. NGS technologies have enhanced the throughput and speed of sequencing combined with bringing down the overall cost of the process over a time. The major applications of NGS technologies being genome sequencing and resequencing, transcriptomics, metagenomics in relation to plant–microbe interactions, exon and genome capturing, development of molecular markers and evolutionary studies. In this review, we present a broader picture of evolution of NGS tools, its various applications in crop plants, and future prospects of the technology for crop improvement.

Introduction

The overall growth, development and behavioural characteristics of every living creature are largely determined by its genetic constitution. Subsequent to the famous double-helix model of DNA, proposed by Watson and Crick (1953), scientists began to find the ways and means to determine the nucleotide sequence of DNA. The first significant breakthrough in this area was achieved in late 1970s when two groups working independently reported two different approaches for DNA sequencing (Maxam and Gilbert, 1977; Sanger *et al.*, 1977). Though Maxam and Gilbert's approach for DNA sequencing was preferred initially, it was Sanger's sequencing technology which subsequently got popularized among the scientific community. The classical genome sequencing projects such as the Human Genome Project (HGP), the *Arabidopsis* Genome Initiative and the International Rice Genome Sequencing Project were successfully completed using Sanger's sequencing approach. Subsequently, many plant genomes were sequenced using this sequencing technology. Though Sanger's dideoxy sequencing method is considered as gold standard with respect to genome sequencing, there

are many shortcomings in this approach. The important shortcomings of Sanger's sequencing method are that it is time-consuming, low throughput and high cost, and needs more labour, *in vivo* cloning of DNA fragments, etc. Therefore, scientists and bioengineers tried to develop new sequencing techniques also known as second-generation (2GS) or next-generation sequencing (NGS) technologies. The success in this direction was reported in 2005, when the first NGS system was developed by 454 and commercialized by Roche as the GS20 (Margulies *et al.*, 2005). Subsequently, many NGS/2GS systems have been reported, which include Solexa GA2 (now Illumina), Applied Biosystem's SOLiD and Ion Torrent www.appliedbiosystems.com; www.illumina.com; www.iontorrent.com).

The developments in the field of NGS technologies have led to a revolution in the field of genetics and genomics. In spite of their inherent limitation of producing shorter reads with higher error rates than Sanger sequencing, NGS technologies are still gaining popularity, largely due to their ability to produce massive quantities of data at a relatively low cost and in a short time period. Further developments in NGS technologies have consistently led to increased read lengths and this is an active area of research in the future of NGS technologies. The present review compiles the different NGS technologies and their applications in the field of plant biology with special emphasis on agricultural plants (Fig. 1.1). In this review we focused primarily on the crop genomes giving weightage to genome sequencing techniques implied and their challenges, applications of NGS in plant biology with emphasis on agricultural crops and conclude with the future strategies and perspective in the area of plant genomics.

Evolutions of DNA sequencing technology

First generation sequencing technologies

The double helix structure of DNA proposed by Watson and Crick (1953) was the milestone

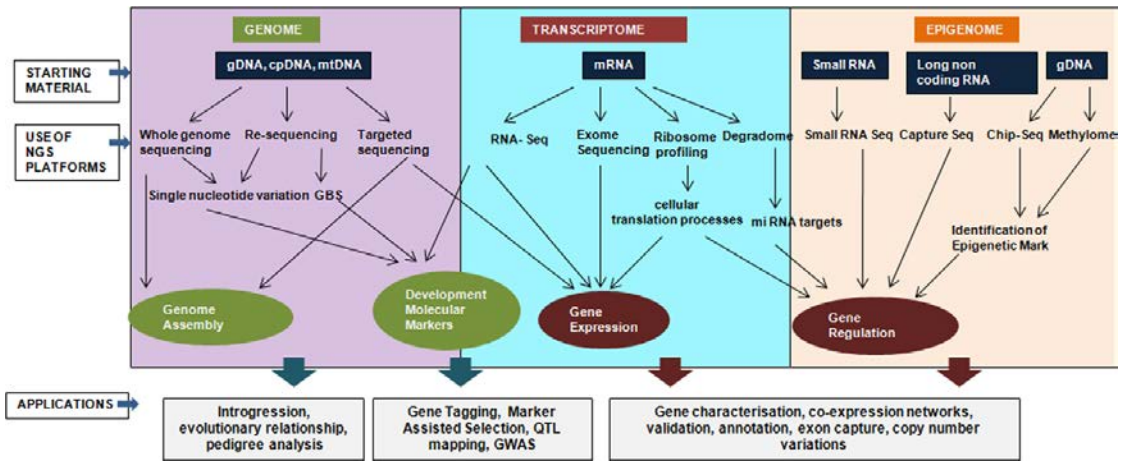

Figure 1.1 NGS platforms as a tool for the plant genomic research. The phenotype of an organism is a manifestation of controlled expression of the underlying gene. The gene(s) expression is largely regulated at three stages: (a) genomic, (b) transcriptomic and (c) epigenetic. For unravelling the complex cellular machinery and its regulatory network the NGS platforms, with suitable modifications, can be utilized at any of these three stages (each stage is represented by different colour boxes). Genomic DNA, chloroplast DNA and mitochondrial DNA are the primary sources of genetic information which can be divulged by NGS assisted whole genome sequencing, high throughput re-sequencing and targeted sequencing. For example, high sequencing coverage obtained by NGS platforms is of great utility in determining the single nucleotide variations (SNVs) in genome which are of immense importance in establishing genotype phenotype relationships. In addition, NGS tools like MethylC-Seq are a 'gold standard' technique for studying genome wide methylation pattern. Similarly, sequencing of mRNA, small RNAs, long non coding RNAs, degradome and exome helps in understating the expression pattern of genes, their spatial and temporal regulations, co-expression networks and association with trait.

in molecular biology research. Subsequently, interest was shifted to decipher the nucleotide sequence of DNA molecules. The first major success in this field was reported simultaneously in 1977 by two independent groups of researchers when two chemistries for DNA sequencing were published (Maxam and Gilbert, 1977; Sanger *et al.*, 1977). Broadly referred to as first-generation sequencing technologies, these two methods utilized different chemistries for DNA sequencing. Due to its complex procedure and low resolution Maxam and Gilbert's method did not gain wide acceptance. Sanger's original dideoxynucleotide (ddNTPs) chain-termination sequencing method was comparatively less cumbersome and relatively accurate but required radiolabelled ddNTPs, and the chemistry involved four separate base specific reactions and autoradiography in order to detect the sequence of DNA molecule. Sanger's method was later on modified and improved. An account of improvement and evolution of Sanger's method can be found in previous reviews (França *et al.*, 2002; Ansorge, 2009; Mardis, 2013).

Second-generation sequencing technologies

Second-generation sequencing technologies were capitalized by Illumina Genome Analyzer, Roche/454 FLX, Life technologies SOLiD and Ion Torrent PGM. Second-generation sequencers omitted the need of *in vivo* cloning, and here DNA can directly be fragmented to produce sequencing libraries of appropriate sizes *in vitro* by adapter ligated amplification using a PCR-based system. PCR-based amplification is required to produce millions of copies of the original DNA fragment, required to produce signal intensity sufficient to detect the incorporated bases during sequencing steps. Second-generation sequencing technologies are divided in two categories on the basis of reaction chemistry they use: (a) sequencing by synthesis used by Illumina, Roche/454 and Ion Torrent and (b) sequencing by ligation used by ABI's SOLiD sequencers.

Third-generation sequencing technology: single molecule sequencing

Third-generation sequencing (3GS) technology differs from second-generation sequencing (2GS) technologies as it does not require the amplification step, leading to elimination of inclusion errors incurred by polymerase during library preparation. Second-generation sequencers use a cyclic wash-and-scan method, and as the number of washing and imaging cycles increases, addition of nucleotides becomes more asynchronous which increases sequencing errors and signal to noise ratio. This particularly limits the read length produced by second-generation sequencers. The advantage of some single molecule sequencing platforms is the ability to detect epigenetic modifications in the genome, which are largely diluted due to amplification step involved in 2GS techniques (Munera *et al.*, 2012). Also, the short reads generated by the 2GS technologies imposes problems in accurate *de novo* genome assembly, repetitive elements and large structural variation analyses (Fan *et al.*, 2010; Delcher *et al.*, 2010). The longer reads generated by third-generation sequencer helps in *de novo* genome sequencing and assembly, improving old assemblies, allowing more accurate analysis of structural variation within the genome and more contiguous reconstruction of genomes which were limited in second-generation sequencers (Carneiro *et al.*, 2013). At present, the major challenge with the single molecule sequencers is inherent higher error rate due to limited ability of detectors to identify and interpret very low levels of signal generated from individual molecules. The 3GS techniques are Pacific Biosciences Single Molecule Real Time sequencers (SMRT) and Helicos Genetic analysis system True single molecule sequencing (tSMS). Pacific Biosciences SMRT was the first 3GS technology to hit the market in 2010. With an improved chemistry (C4), the average read length of PacBio RS II system is over 10 kb and can generate 1 Gb of data per run. In sequel platform PacBio has increased the ZMWs density of loading of samples due to which the data output has increased drastically up to 5–10 Gb per run. Since this technology uses single DNA polymerase per ZMW, total length of a read is dependent on lifespan of the polymerase. Single molecule sequencers suffers from higher raw data error rate, which accounts for up to 15% of incorporated bases, however, this error rate can be minimized by multiple sequencing of same template. The tSMS from Helicos Genetic analysis system was the first commercially available true single molecule sequencing system based on

sequencing by synthesis chemistry. This platform can produce average read length of 30 bases. This platform suffers from higher deletion rate ranging from 1 to 5%, which can be reduced by sequencing from both the ends of a fragment (Buzby *et al.*, 2008).

Fourth-generation sequencing technologies: nanopore sequencing

Fourth-generation sequencing (4GS) technologies omit the use of labelled nucleotides and does not rely on an optical system to detect incorporated nucleotides and also there is no need for the synchronous reagent addition and wash steps. This technology uses the electronic or chemical properties of each nucleotide to determine the sequence of DNA as it is threaded through a nanopore. Current nanopore sequencing technologies use the ionic current blockage method. Currently two nanopore-based systems, biological and solid-state, are being developed and refined. Oxford Nanopore technology has released MinION for test users which will be launched for commercial application. It is small, USB powered, easy to carry equipment. It can produce average read length of 5.4 kb and go up to 10 kb (www.nature.com/news/data-from-pocket-sized-genome-sequencer-unveiled-1.14724).

NGS and plant genomics

Plants being the ultimate source of food and metabolic energy for nearly all animals, cannot manufacture their own food, but also provide sustenance, shelter, clothing, medicines, fuels, and the raw materials from which innumerable other products are made. The plant kingdom is filled with amazingly incomparable diversity and significance (Schatz *et al.*, 2010) pertaining to which sequencing of plant genomes is of great importance. Out of the hundreds of thousands of plant species around the world, only few of them have been sequenced (Michael and Van Buren, 2015; Table 1.1).

Genomics of plants

Advanced high-throughput genome sequencing techniques have proved to be a boon in providing practical solutions to the challenges in the field of genomics, especially crops. The plant kingdom is majorly divided into spore bearing vascular plants and seed bearing vascular plants. The former is further classified into algae, mosses/liverworts and ferns, and the latter into non flowering (gymnosperms) and flowering (all angiosperms) plants. Since the first published genome sequence of *Arabidopsis thaliana* (Arabidopsis Genome Initiative, 2000), a large number of plant genomes belonging to different phylum have been sequenced and published using both first-generation and NGS technologies (Turktas *et al.*, 2015).

Sequenced plant genomes: links from vascular plants to angiosperms

The genome sequences of *Chlamydomonas reinhardtii* (120 Mb) and *Volvox carteri* (138 Mb) are amongst the first multi- and unicellular algae species, respectively (Merchant *et al.*, 2007; Prochnik *et al.*, 2010). Amongst the mosses, the genome of *Physcomitrella* with an assembled genome size of 500 Mb (Rensing *et al.*, 2008) and *Selaginella moellendorffii*, the first non-seed plant genome reported with an assembled genome size of 212.6 Mb (Banks *et al.*, 2011), are breakthrough model organisms in order to study the evolution of vascular land plants and their divergence. Further for a better understanding of the evolution of plants, the genome sequence information from other taxa, especially charophytes, ferns and gymnosperms, could serve as key references. In this context the three gymnosperm (conifer) genome sequences published recently, viz. the genome of Norway spruce (*Picea abies*) with an assembled size of 19.6 Gb (Nystedt *et al.*, 2013) is the first available gymnosperm sequence followed by the loblolly pine (*Pinus taeda*) genome (Zimin *et al.*, 2014; Neale *et al.*, 2014) and white spruce (*Picea glauca*) genome (Birol *et al.*, 2013) with an assembled genome size of 22 Gb and 20.8 Gb, respectively. These genomes helped to understand the divergence of angiosperms and gymnosperms (350 Myr ago) (Jiao *et al.*, 2011).

The development of water-conducting xylem cells and the reproductive development are the two major differences between angiosperms and gymnosperms. Nystedt *et al.* (2013) compared seven genomes, two from the basal plants and five from angiosperms and identified 1021 *P. abies*-specific gene families. *P. abies* homologs present in the angiosperms revealed that gymnosperms lack orthologues of flowering-responsible phosphatidylethanolamine-binding protein (PEBP) protein. Sequencing of angiosperm

Table 1.1 Details of plant genomes sequenced and published during 2015 to 2016

Number	Scientific name	Common name	Genome size (Mb)	Type	Reference
1	*Vigna angularis*	Adzuki bean	538	Dicot	Kang *et al*., 2015
2	*Thlaspi arvense*	Field pennycress	539	Dicot	Dorn *et al*., 2015
3	*Primula veris*	Cowslip	480	Dicot	Nowak *et al*., 2015

genomes thus additionally served and immensely helped in understanding their divergence from rest of the plant genomes. With over 100 plant genome sequence data already published (Michael and Van Buren, 2015; https://genomevolution.org/wiki/index.php/Sequenced_plant_genomes), it is possible to study their complex life cycle, evolutionary history and genome structural organization. The crops and model plant genomes such as *Arabidopsis, Brachypodium distachyon, Physcomitrella patens* and *Setaria italica, Oryza sativa, Populus trichocarpa, Zea mays, Glycine max, Solanum lycopersicum* and *Pinus taeda* are extremely vital not just as crops but as functional models to enable genome-wide studies of various key genes/gene families, pathways and important traits (Arabidopsis Genome Initiative, 2000; Vogel *et al*., 2010; Rensing *et al*., 2008; Bennetzen *et al*., 2012; Zhang *et al*., 2012a; Goff *et al*., 2002; Yu *et al*., 2002; Tuskan *et al*., 2006; Schnable *et al*., 2009; Schmutz *et al*., 2010; Tomato Genome Consortium, 2012; Zimin *et al*., 2014). Nevertheless, non-functional models and non-crop plants serve as sources to explore the evolution of flowering plants and an in-depth understanding of plant genome architecture. The genome sequences of non-functional model plants like *Utricularia gibba* (bladderwort; 77 Mb), *Genlisea aurea* (corkscrew; 43.4 Mb), an aquatic non-grass monocot *Spirodela polyrhiza* (greater duckweed; 158 Mb), *Selaginella moellendorffii* (212.6 Mb), and *Amborella trichopoda* (870 Mb) are available (Banks *et al*., 2011; Albert *et al*., 2013; Ibarra-Laclette *et al*., 2013; Leushkin *et al*., 2013; Wang *et al*., 2014). These can help to identify the whole evolutionary link between basal vascular plants and the most complicated and diverse angiosperms. Most importantly, it can help in identifying plant-specific gene families responsible for the specialized characteristic of each family and genus of the plant kingdom.

Role of third-generation sequencing platforms in decoding plant genomes

We have seen a generation of large volumes of sequencing information through NGS and assembly platforms. Although NGS systems producing up to 100 Gb of data per run have advanced genome information (Imelfort and Edwards, 2009; Mardis, 2008; Schatz *et al*., 2010; The 1000 Genomes Project Consortium, 2010), the diversity and variations of different genomes and short read lengths from NGS make it difficult to achieve a complete published genome information. Therefore, taking DNA sequencing to a further level and dramatically reducing costs, several companies have hit the market with the third-generation sequencing (3GS) technologies. The remarkable quality of genome sequences produced by 3GS and mapping technologies are hundreds to thousands of times more contiguous and enable improved analysis of nearly every aspect of the genome. The genomes are more complete and show accurate representation of genes, regulatory regions and other important genomic elements, as well as better resolution of the overall chromosome organization (Burton *et*

al., 2013; Roberts *et al.*, 2013; Ross *et al.*, 2013; Cao *et al.*, 2014; Pendleton *et al.*, 2015; Lee *et al.*, 2016).

Next-generation sequencing and plant transcriptome analysis

The rapid developments in NGS technologies have revolutionized the field of plant transcriptomics, specifically in those plants where no genome sequence information is available. The NGS-based RNA sequencing technologies are generally called mRNA-seq tools. These technologies provide a novel method for identifying, mapping, and quantifying transcriptomes under different developmental stages and stress conditions. Deep RNA sequencing is a powerful tool for comparing gene expression analysis and discovering the full length 5′ and 3′ untranslated regions, novel splice junctions and transcripts, alternative transcription start sites, and rare transcripts (Cloonan *et al.*, 2008; Mortazavi *et al.*, 2008; Wilhelm *et al.*, 2008; Zhang *et al.*, 2010; Fig. 1.2). RNA-seq data with both technical and biological replicates show good level of reproducibility (Cloonan *et al.*, 2008). The transcribed RNA from genomic DNA, besides coding for proteins, also has potential non-coding RNAs. Owing to their significance in regulation of gene expression, these non-coding RNA have attracted great attention in recent past.

Applications of transcriptome profiling and long non-coding RNA (lncRNA) in plant

Cereals

A large number of studies are carried out to generate transcriptomes from cereal crops. RNA-seq was used to understand the transcriptional regulatory network of *Opaque2* (*O2*). *O2* transcription factor in maize plays an important role as a central regulatory molecule during maize endosperm development by regulating multiple regulatory pathways (Li *et al.*, 2015). The RNA-seq analysis found 1605 differentially expressed genes and 383 differentially expressed long, non-coding RNAs between wild-type and *O2* endosperms, 15 days after pollination. Transcriptome sequencing in rice was used to study differentially expressed genes

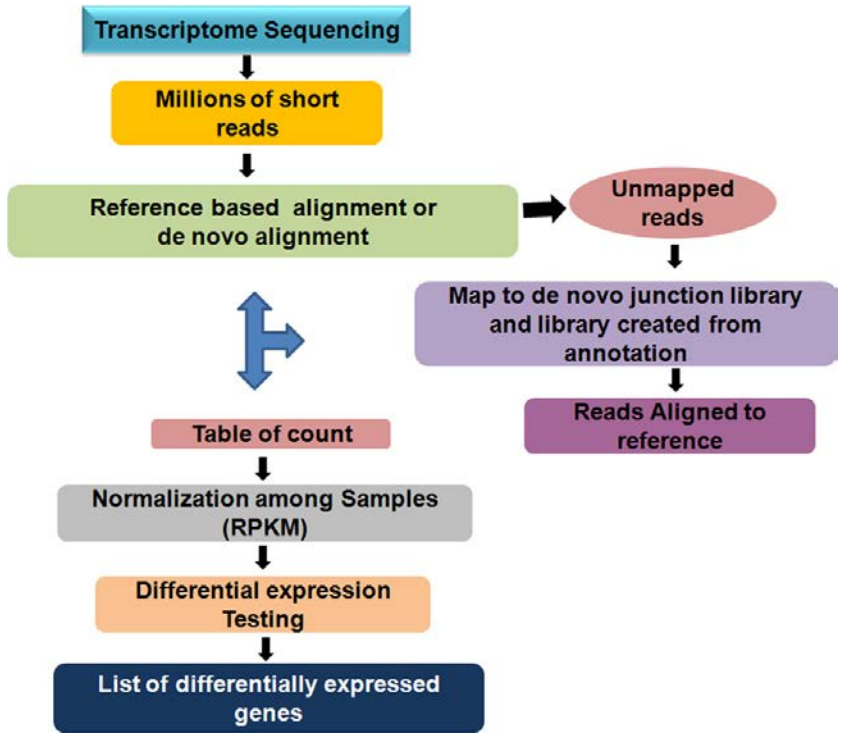

Figure 1.2 Pipeline for transcriptome sequencing using NGS techniques.

(DEGs) upon infection with *Magnaporthe oryzae* and to probe the molecular response of rice to *Ustilaginoidea virens* infection (Kawahara *et al.*, 2012; Bagnaresi *et al.*, 2012; Chao *et al.*, 2014). Similarly, genome-wide transcription profiling of primed (Selenium and salicylic acid priming) and non-primed seedlings of rice was reported (Hussain *et al.*, 2016). Transcriptome of bread wheat provided a methodology for homeolog-specific sequence assembly (Schreiber *et al.*, 2012) and deep transcriptome sequencing of a wheat genome was used to construct a fine transcriptome map of the chromosome 3B (Pingault *et al.*, 2015). A NGS tool was also used in barley, finger millet and sorghum to study transcriptomes under different conditions (Bedada *et al.*, 2014; Rahman *et al.*, 2014; Tombuloglu *et al.*, 2015; Abdel-Ghany *et al.*, 2016).

Though many studies were conducted to profile the mRNA transcriptome of cereals using NGS technology, very few studies are available wherein NGS has been used for profiling of lncRNA. These studies include genome-wide analysis of non-coding parts of transcriptomes uncovering lncRNA in maize as well as rice and discovered long intergenic non-coding RNAs (lincRNA) which contain SNP associated with agriculturally important traits in maize and two lincRNAs in rice (Kim *et al.*, 2012; Wang *et al.*, 2015a).

Pulses and oilseeds

Many studies of NGS applications in pulse crops are being reported in last few years. RNA-seq is successively used in chickpea, lentil, *Medicago truncatula* and *Vigna unguiculata* to identify developmental stage-specific transcriptomes, drought and salinity responsive transcriptomes, development of large scale genomics resources in lentil such as unigenes and 2393 EST-SSRs, to identify osmotic stress related lncRNAs and to generate a gene expression atlas of different plant tissues (Singh and Jain, 2014; Wang *et al.*, 2015b; Garg *et al.*, 2016; Yao *et al.*, 2016)

NGS technology has been used in oil-producing plants to study the transcriptome dynamics under different conditions. In soybean, RNA-seq atlas was built using NGS (Severin *et al.*, 2010). Transcriptome profiling of peanut, *Brassica napus* and sunflower was performed to identify various biochemical pathways. Further novel lncRNAs of *Brassica napus* in response to *Sclerotenia sclerotiorum* infection were identified. NGS technology was also used to understand the molecular basis of a higher rate of recombination in cultivated genotypes during meiosis as compared to their wild ancestors in sunflower (Joshi *et al.*, 2016; Florez-Zapata *et al.*, 2016).

Horticulture and ornamental crops

Li *et al.* (2012) identified 92 DEGs that were associated with the metabolism and anthocyanin synthesis during fruit ripening. Rowland *et al.* (2012) analysed transcriptomes of different blueberry tissues to identify genes that were associated with cold acclimation and fruit development. Various other transcriptome studies involving fruits, flowers and vegetables crops are given Table 1.2.

Commercial crops

Cotton is an important fibre crops in India that has high commercial value. In the study aimed at analysing the lncRNAs in cotton, Wang *et al.* (2015c) characterized lncRNAs in *Gossypium* species. Recently, Lu *et al.* (2016) identified 10,820 lncRNAs that were associated with different abiotic stresses. Similarly, Zou *et al.* (2016) also identified a total of 5996 lncRNAs that were reported rapid and dynamic changes during early fibre and rapid elongation stages. NGS techniques were used for discovery of genes, regulatory sequences and non-coding RNA for the improvement of sugarcane as a biofuel crop. In a recent study, six genotypes of sugarcane were studied and a total of 72,269 unigenes were identified. Out of which more than 28,788 of these unigenes showed significant similarity to sorghum proteins indicating that both species share a higher degree of genetic lineage. In another study, transcriptome analysis of sugarcane during smut pathogen infection (*Sporisorium scitamineum*) identified 65,852 unigenes and most of the DEGs were related to metabolic pathways in resistant and susceptible genotypes (Que *et al.*, 2014).

Recently, lncRNAs have been found to play an important role in gene regulation by acting as endogenous target mimics. The size of lncRNAs is usually more than 200 nucleotides in length (Chen, 2009; Rinn and Chang, 2012). In plants, identification of long non-coding RNA is more recent and not as comprehensive compared to other eukaryotes (Ulitsky and Bartel, 2013; Zhang *et al.*, 2014). Non-coding RNA regulates the expression

Table 1.2 List of mRNA and lncRNA studies and NGS platforms used for sequencing in different crops

Number	Crop	Platform	Validation method	Condition	Reference
1	*Glycine max*	Illumina	–	Fourteen diverse tissues	Severin *et al*., 2010

level of target genes via various molecular mechanisms (Quan *et al.,* 2015; Zhu and Wang, 2012). lncRNAs act as a regulator in important biological processes by enhancing target site accessibility to RNA polymerases, formation of RNA-dsDNA triplex, inhibition of RNA polymerase activities as well as regulation of transcription factors (Lipshitz *et al.,* 1987; Nguyen *et al.,* 2001; Willingham *et al.,* 2005; Martianov *et al.,* 2007; Hirota *et al.,* 2008; Mariner *et al.,* 2008). They also have a role in post-transcriptional modulations of mRNA. lncRNAs are found to have role in regulating complex gene regulatory networks involved in plant development and stress management (Crespi *et al.,* 1994;

Ding *et al.*, 2012; Heo and Sung, 2011; Zhang *et al.*, 2014).

Identification of small non-coding RNA by NGS technology

Small RNAs (sRNAs) are another important class of RNA molecules of 21–24 bases long and include microRNAs (miRNAs), short interfering RNAs (siRNAs), transacting siRNAs (ta-siRNAs) and cis/trans-natural antisense small-interfering RNAs (nat-siRNAs). These small RNAs are non-coding, essential entities that regulate gene expression in epigenetic processes almost in every domain of life (Ruiz-Ferrer and Voinnet, 2009; Zhang *et al.*, 2011). The sequence alterations in miRNA or other small non coding RNAs can be mapped by genomic sequencing or RNA-seq, while the expression levels can be determined by RNA-seq or deep sequencing or expression microarrays (Singh *et al.*, 2012). The alliance of gene expression data with a small RNA data set will help to understand how different biological processes coordinate together in a cellular context (Jain, 2012). In recent times, a large number of studies involving NGS technology have been reported primarily to identify novel as well as conserve miRNA, along with their targets under different stresses or developmentally regulated conditions (Table 1.3) sRNAome analysis of *Arabidopsis thaliana* revealed while expression of miR156, miR399, miR778, miR827, and miR2111 was induced, yet, expression of miR169, miR395, and miR398 was repressed under phosphate (Pi) deficiency indicating that these miRNAs may be involved in Pi uptake in *Arabidopsis* (Hsieh *et al.*, 2009). In *Brachypodium distachyon*, a model crop, three conserved and 25 novel miRNAs showed significant change of expression in response to cold stress and differential expression profiling of 94 conserved miRNAs from 28 families during vegetative and reproductive tissues (Zhang *et al.*, 2009; Wei *et al.*, 2009). A review describing the study of various aspects of miRNA using deep sequencing tools was documented for further information (Yang and Li, 2012).

Agricultural crops

Rice being a major cereal crop, various transcriptome studies to identify non-coding RNAs have been reported. NGS was used to categorize different classes of small RNA regulatory elements from mature rice grain and seedlings (Heisel *et al.*, 2008; Guo *et al.*, 2012; Campo *et al.*, 2013; Li *et al.*, 2014). These studies together signified the role of miRNAs in rice blast disease and stripe virus resistance. Besides biotic factors, a study involving abiotic stresses has also been reported and elucidated 294 known and 539 novel heat-responsive miRNAs during heat stress (Li *et al.*, 2015b).

In maize, the epigenome was critically scrutinized by NGS technologies for its relationships to mRNA and small RNA transcriptomes (Wang *et al.*, 2009; Liu *et al.*, 2014; Zhou *et al.*, 2016) to understand the molecular aspects underlying maize ear development and to elucidate the rice *black-streaked dwarf* virus-responsive pathway in maize.

Wheat being hexaploid, its genome is considered to be genetically complex. In an earlier NGS-based study on wheat, 58 miRNAs comprising 43 miRNA families were identified, of which 20 families were conserved and 23 were found to be novel (Yao *et al.*, 2007). Further, in another study, 170 conserved miRNAs representing 25 families and 23 novel miRNAs were also identified (Wei *et al.*, 2009). Further, in wheat, a total of 2076 small RNAs were identified (Yao *et al.*, 2010). Similarly a set of wheat miRNAs which play roles in regulating wheat response to powdery mildew pathogen *Erysiphe graminis* f. sp. *tritici* and heat stress were also identified using high-throughput sequencing (Xin *et al.*, 2010). Tang *et al.* (2012) analysed the male sterility system of thermosensitive genic male sterile (TGMS) lines of wheat and concluded that miR167 and tasiRNA-ARF play a role in the developmental response to cold stress and the regulatory pathways of sRNA that were linked with male sterility. A brief summary of work related to wheat is given in Table 1.3.

Though initial efforts were concentrated to study the small RNAs in cereals, of late efforts are also being made to understand the role of these RNA molecules in pulse, oilseeds and other crops of economic importance. In *Medicago truncatula*, an important model legume, a small RNA library was generated and conserved and novel small RNAs (miR1507, miR2118, miR2119 and miR2199) were identified. They also identified three novel transcripts encoding TIR-NBS-LRR disease resistance (Jagadeeswaran *et al.*, 2009). The miRNA (miR408) could induce drought tolerance in chickpea (Jain *et al.*, 2014; Srivastava *et al.*, 2015;

Table 1.3 Small-RNA studies and NGS platforms used for sequencing in different crops

Number	Crop	Platform used	Validation method	Experimental conditions	Reference
1	*Triticum aestivum* L. line 3338 w	454 Life Sciences™ technology	RNA gel blot analysis and RT-PCR	Wheat and monocot-specific miRNAs	Yao *et al*., 2007

68	*Solanum lycopersicum* 'Rui Xin'	Illumina HiSeq2500	Computational validation	Chilling injury	Zuo *et al*., 2016

Hajyzadeh *et al*., 2015). Similarly novel miRNAs and their targets involved in stress response were also identified in pigeonpea and chickpea (Kompelli *et al*, 2015; Barrera-Figueroa *et al*., 2011).

Oilseed crops, largely grown for human consumption, are important for Indian agriculture. One of the important oilseed crops, soybean, is grown all over the world. To understand the regulatory network of miRNAs and their functions during seed development as well as to the miRNAome profiling associated with abiotic stress responses in soybean, NGS technology was used to identify the differentially expressed miRNAs (Song *et al*., 2011; Li *et al*., 2011b). Besides soybean, members of Brassicaceae family, specifically *Brassica napus*, is a major source of vegetable oil. There are many reports in *Brassica napus*, which used NGS techniques to decipher various molecular mechanisms during different stages of growth, during their interaction with biotic and abiotic stresses, oleic acid content, etc. (Table 1.3). Commercial or cash crops are another important category belonging to agricultural crops. Some of the major crops of India on which miRNA studies have been conducted are cotton (*Gossypium hirsutum*), tea (*Camellia sinensis* L.), *Coffea canephora* and sugarcane. In cotton, using NGS tools, 25 novel miRNAs that were associated with somatic embryogenesis were identified (Yang *et al*., 2013). Similarly, miRNAs in response to drought and salinity stress were also studied in cotton, and miRNAs which played role in drought and fibre development were identified (Xie *et al*., 2015). A brief summary of works is given in Table 1.3.

Horticulture crops

Besides agricultural crops, horticultural crops are also a significant component of farming systems and sources for many dietary supplements. Various studies based on NGS technologies were conducted to identify and characterize miRNAs in these crops (Table 1.3). For instance, miRNAs involved in tomato fruit during ripening, *Phytophthora* infections and cucumber mosaic resistance, and chilling injury were identified (Moxon *et al*., 2008; Luan *et al*., 2015; Zou *et al*., 2016). Similarly, *Verticillium dahlia* responsive miRNAs in *Solanum linnaeanum* (Yang *et al*., 2013), and those involved in drought stress in *Solanum tuberosum* (Lakhotia *et al*., 2014) were also identified. Overall, small non-coding

RNAs is a broad class of regulatory RNAs, and behaves as protein counterparts involved in regulating post transcriptional gene silencing and translational repression. Deep sequencing employs efficient, economical, massive parallel sequencing, generating millions of small RNA sequence reads from a given sample. sRNAome by deep sequencing quantifies absolute abundance and allows for the discovery of novel microRNAs that have escaped previous cloning and standard sequencing efforts (Creighton *et al.*, 2009). Some miRNAs can significantly affect plant traits, including virus resistance, nematode resistance, drought and salinity tolerance, heavy metal detoxification, biomass yield, grain yield, fruit development and flower development. Therefore, miRNAs are considered as a newly identified gene resource for the genetic improvement of crop plants (Zheng and Qu, 2015). Therefore, these all studies which analysed and identified miRNAs have the potential to enhance food security by helping breed crop cultivars with improved agronomic traits (Zhou and Luo, 2013). Studies have indicated that small non-coding RNA loci, like protein-coding genes, could be targets of domestication selection and play an important role in crop domestication, and improvement, abiotic stress, plant–pathogen interactions and breeding useful traits (Ruiz-Ferrer and Voinnet, 2009; Wang *et al.*, 2010).

NGS and metagenomics of plant–microbe interaction

Microbes are the most abundant living organisms on earth. In spite of their abundance, only small fraction of them have been explored and very few of them can be grown in laboratory conditions. Overall, large chunks of the microbial population are out of the reach of scientists largely due to an inability to culture them under laboratory conditions. Quite intriguingly, it has been observed that microorganisms growing on media and those directly obtained from natural samples showed very large differences in their number, displaying so called the great plate count anomaly (Staley *et al.*, 1985). Therefore, lack of standard culture media and growth conditions has largely led to the restricted scientific exploration of these microbial populations. In the context of foregoing observations, it becomes necessary to study the microbial populations in their natural conditions so as to capture the microbial community or metagenome (Woese *et al.*, 1987). Metagenome is the use of advanced techniques to analyse microbial communities taken directly from the natural sources without growing them under laboratory conditions (Chen *et al.*, 2005).

Approaches used in metagenomics

Broadly two approaches are used to study metagenomics, i.e. sequence-based metagenomics and function-based metagenomics. The sequence-based study depends on identifying the complete genetic sequence of microorganisms present in the sample. In most of the studies targeting microbial communities, 16S rRNA gene sequences were used to identify the species. This method is useful to study the evolutionary conservation and phylogenetic analysis of the microbes present in the samples (Claesson *et al.*, 2010; Creer *et al.*, 2016). On the contrary, function-based metagenomics explores the products of the microbial community to study that specific community (Coughlan *et al.*, 2015). Subsequently it was sequencing techniques, particularly the introduction of NGS techniques, that revolutionized the plant–microbial metagenomic studies. This sequencing technology opened a new way for discovering and analysing these organisms at genome level, which is a culture independent technology that utilizes a combination of various research methods, specifically NGS and bioinformatics tools. Plants and microbes are in continuous interaction with each other in the environment. The association of microbes with the plant can be of endophytic (inside the plant) or epiphytic (attached to the plant). Plant–microbial associations could be positive interactions, neutral associations or negative interactions (pathogens). Almost every part of a plant is inhabited by a microbial community, yet rhizosphere and phyllosphere are the major sites for plant microbe interactions for most of the microbes. Microbiota of these two regions (rhizosphere and phyllosphere) are so closely associated with plants that even they are called as second genome of the plant (Berendsen *et al.*, 2012). Several studies have been carried out to analyse the microbiome of various plants sampled from the phyllosphere, rhizosphere, and various parts, and were found beneficial to the plant (Lugtenberg *et al.*, 2009; Porras-Alfaro *et al.*, 2011; Vorholt *et al.*, 2012). The details of the

metagenomics studies aimed at plant–microbial interactions and plant microbiota are given in Tables 1.4 and 1.5. Recently, the 454 NGS technique was used to study the diversity, community structure, and dynamics of endophytic bacteria in different plant species and it found four classes of *Proteobacteria* with *Alphaproteobacteria* as the dominant class and revealed that host plant species had greater influences on type of bacterial communities (Ding and Melcher, 2016).

Besides their application in metagenomics, NGS techniques also have great applications in the study of metatranscriptomics. Metatranscriptomics includes analysis of gene transcripts directly isolated from the entire community of organisms. Metatranscriptome study is also referred to as environmental transcriptomes, microbial community gene expression profiles, microbial community RNAs and whole community transcripts. The metatranscriptome field has opened a door to study various aspects around environmental community, i.e. active community members and metabolic pathways (Urich *et al.*, 2008). The metatranscriptomics approach has been used to identify various genes actively involved in *Eichhornia crassipes* and *Fusarium verticillioidies* association, in strawberry plants for defining the fungal communities associated with different organs of plants (Luo *et al.*, 2015; Abdelfattah *et al.*, 2016). Recently, a study combining NGS and metagenomic analysis was conducted to generate large number of cDNAs using model system tomato pepino mosaic virus. Subsequently, the same approach was used in the study of globe amaranth (*Gomphrena globose*) infected with an unknown pathogen. Therefore, this method hastens the process of development of routine assays for new viral pathogens (Adams *et al.*, 2009).

NGS technique was also used for sequencing whole viral genomes to undertake plant metagenomic studies to discover new viruses. Adams *et al.* (2013) identified the presence of *Maize chlorotic mottle virus* and *Sugarcane mosaic virus*, causal agents

of lethal necrosis in Kenyan maize using NGS (Wangai *et al.*, 2016). A detailed review describing the various roles of NGS in viral diagnostics has already been published by Boonham *et al.* (2014).

NGS technology has also been used successfully to determine the begomoviral genome and their associated satellites from begomovirus-affected tomato and okra plants by using metagenomics (Idris *et al.*, 2014). In another study, NGS and metagenomics approaches together were used to study native bacterial microflora diversity in different anatomical organs of *Solanum lycopersicum* (Ottesen *et al.*, 2013). In tomato, the root microbiome was studied in order to understand the endophytes and their association with root-knot nematodes (*Meloidogyne* spp.) (Tian *et al.*, 2015). Similarly in rice, a metagenomic rice endophyte DNA library was constructed and further 16S rRNA gene sequence information was studied (Sessitsch *et al.*, 2012). Similarly, metagenomic analysis of olive-knot to decipher the role of different bacterial species in the disease establishment has been reported (Passos da Silva *et al.*, 2014). Even the role of the enzymatic repertoire (glycoside hydrolases) of a microbial community in degradation of crude cotton biomass was reported using NGS-based metagenomics approach (Zhang *et al.*, 2016).

NGS applications in exome and captured sequencing

Selection of genomic regions of interest and enrichment of these regions is called captured sequencing. This technology is a revolutionary process for the selective enrichment of targeted genomic regions from the complex genomic DNA. Targeted-capture is used to enrich the sequences of interest before carrying out NGS, such as repetitive sequences (Syring *et al.*, 2016), exome (Neves *et al.*, 2013), and gene space regions (Zhou and Holliday, 2012). This technology permits the isolation of target loci from the background of the entire genome. In comparison with other sequencing technologies, captured sequencing is inexpensive, quick and simple. The scale of capture can range from several targeted loci to over a million target regions (Agilent 2011; Microarray 2011; NimbleGen 2011), making it adaptable for both small-scale and large scale projects. This technology holds promise for plant genomes because they are large, complex

and contain a large amount of repetitive elements. In the present review, we are focusing on captured sequencing and exome sequencing. Exome are comprised of those sequences in DNA that code for a protein. It may also include the functional non-protein-coding sequences such as micro-RNAs, long intergenic non-coding RNA, etc. as well as specific candidate regions. The technique to select and enrich the exomes followed by their sequencing using NGS technology is called exome sequencing (Warr *et al.*, 2015). Initially, PCR was widely used to capture the sequence (Mamanova *et al.*, 2010), followed by circularization of capture sequences using a suitable circularization technique such as molecular inversion probes (Nilsson *et al*, 1994) and spacer multiplex amplification reaction (Krishnakumar *et al.*, 2008), and hybridisation capture methods such as array-based hybrid selection (Albert *et al.*, 2007; Okou *et al.*, 2007) and solution hybridization capture (Gnirke *et al.*, 2009).

Captured and exome sequencing studies across different crops

Application of this approach has gained momentum in plant systems recently. Targeted sequencing has been done in several crop and tree species using the captured method of sequencing (Table 1.6). Captured sequencing has been used to identify DNA polymorphisms in many polyploidy crop species. It is a powerful tool for studying evolution, population genetics and phylogeographic studies (Carstens *et al.*, 2013; Smith *et al.*, 2014; McCormack *et al.*, 2015). Various targeted studies conducted using NGS techniques have been detailed in Table 1.6.

Exome sequencing is most widely used targeted sequencing method that aims only an informative subset of the genome which varied between 1% and 2% of the genome. Saintenac *et al.* (2011) captured 3.5 Mb of the exonic sequence with coverage of 3.5–7.0% of the exome and studied 3497 genes in durum wheat accessions. In the subsequent year, a novel exome capturing protocol for wheat based on a NimbleGen array was developed by Winfield *et al.* (2012). This protocol was used to sequence exomes of the eight wheat accessions by capturing a 56.5 Mb genomic region to identify SNPs for the genotypic classification of a segregating locus in polyploid wheat (Allen *et al.*, 2013). Other studies in rice and wheat include screening of novel mutations of rice and durum wheat, targeted capture of 107 Mb of non-redundant regions in 62 lines of wheat, exome capture for rapid cloning of *R*-genes in hexaploid bread wheat and exome sequencing in the genomes of rice somaclonal variant (salt-tolerant and drought-tolerant) and parental cultivar (Henry *et al.*, 2014; Udomchalothorn *et al.*, 2014; Jordan *et al.*, 2015; King *et al.*, 2015; Steuernagel *et al.*, 2016).

In maize, exome capture was performed to understand endosperm filling and maturation and to create a population of 1788 lines (Jia *et al.*, 2016). Exome capture kit has also been developed for barley (*Hordeum vulgare* L.) to selectively enrich 61.6 Mb of protein coding sequence (Mascher *et al.*, 2013) which was used for sequencing of exome X-ray mutagenized mutants and wild type genotypes to identify a candidate gene HvMND belonging to the CYP78A family that may affect

Table 1.6 Plant genome capturing studies performed using NGS platforms

Number	Plant	Genome coverage	Method	Reference
1	*Triticum aestivum*	56.5 Mb	Nimblegen Array technology	Winfield *et al*., 2012
2	*Populus trichocarpa* (black cottonwood)	20.76 Mb	Agilent technologies	Zhou *et al*., 2012
3	*Saccharum officinarum*	5.8 Mb	SureSelect Target Enrichment System	Bundock *et al*., 2012
4	*Saccharum hybrid*	5.8 Mb	SureSelect Target Enrichment System	Bundock *et al*., 2012

many agricultural traits (Mascher *et al.*, 2014). Kono *et al.* (2016) discovered the distribution of hundreds of SNPs in cultivated and wild accessions of barley and soybean using exome sequencing. *Hordium bulbosum* is the wild relative of cultivated barley that has superior pathogen resistance and stress tolerance which can be crossed to cultivated barley genotype. There was lack of suitable molecular tools to characterize the genetic introgressions from *H. bulbosum* in order to select the beneficial variants and exclude the variants that were not important from breeding point of view. Recently many exome capture studies were reported in this crop for the development of genic markers and genome introgression studies (Wendler *et al.*, 2014, 2015). Russell *et al.* (2016) studied the environmental adaptation in the georeferenced landraces and wild accessions by exome capture.

Besides, exome capturing in switchgrass *(Panicum virgatum)*, a potential biofuel feedstock crop, allowed assessment of the genome variation in its two primary ecotypes and identification of variation in *CONSTANS (CO)* and *EARLY HEADING DATE 1 (EHD1)* genes (Evans *et al.*, 2014, 2015). Exome sequencing has also been reported in Eucalypts, black spruce (*Picea mariana*) and black cottonwood (*Populus trichocarpa*) (Zhou and Holliday, 2012; Dasgupta *et al.*, 2015; Pavy *et al.*, 2016) primarily to study the genetic variation.

Next-genomics sequencing and molecular markers

The discovery and application of molecular markers for the detection and exploitation of DNA polymorphism is one of the most significant achievements in the area of molecular genetics and plant breeding. Applicability of these markers depends on various factors, viz. its physical properties and genomic location, the cost involved, ease of use, and degree of throughput required (Jonah *et al.*, 2011). Molecular markers are generally categorized into two groups, macro-molecules (proteins and deoxyribonucleic acid) and biochemical constituents (secondary metabolites in plants). Secondary metabolites are restricted to the plants and its applicability is not as wide as DNA makers (Joshi *et al.*, 2011). Among the macro-molecules, availability of protein markers is very limited and its analysis is difficult and more tedious than DNA markers. Among all the molecular markers, DNA markers are the most commonly used markers in the field of molecular genetics and plant breeding for various purposes. Single nucleotide polymorphisms (SNPs) have been recognized as potential markers of choice for genome-wide studies due to even distribution throughout the genome (like simple sequence repeats, SSRs), having the advantage over SSRs of being easily typed in large numbers (in high-throughput manner), and signifying variation in both coding and noncoding regions of the genome (Altshuler *et al.*, 2000; Brumfield *et al.*, 2003; Slate *et al.*, 2009). With the advancement of genome sequencing technologies, molecular markers with a known genomic location are becoming more useful and applicable. The existence of various kinds of molecular markers, and differences in their principles, methodological adaptability, and application's suitability need cautious consideration in opting for one or more of such methods for crop improvement programmes. However, these markers are generally based on electrophoretic resolution of DNA fragments, which limits capturing of genetic differences and also this method cannot resolve genetic polymorphisms with less than 5 bp differences (Semagn *et al.*, 2006). Genotyping of considerably large plant populations may take longer duration depending on how to do, what kind of maker system to adopt and how much throughput the adopted system could generate. NGS technology fulfils all the demands of the coming age plant breeding experiments. It is an efficient technology to develop low cost, high-throughput molecular markers for genotyping of such a large plant population in a short period. Using the NGS technologies, several molecular markers were developed to decipher the complex sequences at thousand loci in the genome of all the individuals of a large plant population sample. These NGS technologies include reduced-representation libraries (RRLs; Gore *et al.*, 2009; Hyten *et al.*, 2010), complexity reduction of polymorphic sequences (CRoPS; Mammadov *et al.*, 2010), low coverage multiplexed shotgun genotyping (MSG; Andolfatto *et al.*, 2011), restriction-site associated DNA sequencing (RAD-seq; Pfender *et al.*, 2011), genotyping by sequencing (GBS; Elshire *et al.*, 2011), high-density array (HDR) genotyping (Gunderson, 2009), and sequence-based polymorphic (SBP) marker technology (Sahu *et al.*, 2012).

All of these methods comprise the following basic steps: the digestion of multiple samples of genomic DNA extracted from individuals or set of populations with one or more restriction enzymes; a selection or reduction of the resulting restriction fragments; and NGS of the final set of selected fragments, which should be less than 1 kb in size (avoiding the read-length limits of most of current NGS platforms, except PacBio); bioinformatic analysis to study the association between traits and called variants; and ultimately infer the biological importance from the analysed dataset. Variations in the resulting sequenced fragments can be used as molecular markers in crop breeding programmes (Davey *et al.*, 2011). Though NGS-based markers have enhanced crop breeding programmes, still there are challenges in high-throughput marker generation. These are posed in the form of a way to design the experiment, how many individuals to be screened, which NGS platform and method will be well-suited to minimize the per-sample sequencing cost, etc.

Major applications of high-throughput markers in crop plants

A wide range of applications and methodologies of genetic markers has been reported in various crop plants (Semagn *et al.*, 2006). Molecular plant breeding aims to improve crop variety in terms of its quantity and quality by applying the latest inventions made in the fields of genetics and genomics. Our understanding about the relationship between genotype and phenotype has been continuously increasing with the help of advanced genomics tools. Some of these applications include (i) surveying allelic diversity in breeding material or natural populations to select the desired genotypes; (ii) marker-assisted selection (MAS) strategies for variety development and germplasm improvement; and (iii) gene pyramiding for gathering multiple agronomically desirable genes within the same cultivar (Jain *et al.*, 2002; Gupta and Varshney, 2004). Of these several applications, one of the major applications of markers are identification of DNA sequences associated with desired traits in crop breeding. This type of application has been described in several crop breeding programmes and greatly benefited the plant breeders in the easy selection of genotypes where phenotypic expressions become difficult to detect individually with utmost breeding value. These expressions may be hindered by many factors such as tissue and age of plant, environmental conditions, expression observing methods and time-frame of expression. These constraints can be easily avoided by the application of molecular markers in selection of genotypes with particular trait(s). Some major applications of high-throughput marker technologies are given with separate subheadings.

Resequencing, genotyping and diversity analysis

High-throughput genotyping derived from NGS is one of the major applications of molecular markers. Approximately seven million plant accessions, including wild relatives, landraces and human-made advanced varieties/cultivars have been preserved in several, around 1750 national and international, gene banks worldwide (FAO, 2010) and it is a well-known fact that the whole world is dependent on these plants for food, fibre and fuel. Therefore, it is very important for biologists to characterize these accessions and make them available for further crop improvement programmes. In this order, McCouch *et al.* (2012) presented a vision for the potential of genotyping at large-scales such as gene bank collections. In this vision, authors also outlined the constraints in genotyping work at the gene bank level and suggested that applications of NGS may solve many problems related to genetic characterization efforts in gene banks. These major challenges include the need to correctly identify accessions and eliminate duplicate accessions from gene bank collections. Such characterization work has begun with rice genomics, whereby 3000 rice genotypes have been characterized, including identification of SNPs and other structural variations of the genome (3K RGP, 2014). However, almost every county has legal provision to protect the country's genetic resources by not moving or transferring any such materials without approval of the competent institutions or genetic resource management governing body of the country.

Linkage and association mapping

With the use of NGS and genotyping technologies, it is possible to develop high-throughput molecular markers as well as assume genotyping at large scale in both major and minor genes that can be exercised

for generating high-resolution genetic and physical maps. Meanwhile, these approaches can also be exploited to identify genetic variation in germplasm collections of cultivars, landraces and wild species. This genetic variation can be introgressed in elite cultivar or genotype of interest through linkage and association mapping approaches. Moreover, the major genes or superior alleles of the genes or QTLs for the desirable traits can also be identified and introgressed or pyramided in elite cultivars or genotypes of interest using advanced plant breeding approaches such as marker-assisted back crossing (MABC), marker-assisted recurrent selection (MARS), advanced-backcross QTL (AB-QTL), multi-parent advanced generation intercross (MAGIC), or genome-wide selection (GWS) (Varshney and Dubey, 2009).

Phylogenetic and evolutionary studies

Before the development of NGS technologies, large-scale genome-wide studies were restricted to a few model organisms whose genomes were sequenced. During that time whole genome sequencing was very time-consuming and a laborious project and it was done with collaboration of many countries. Now, the scenario is totally different and even a single laboratory may afford the whole sequencing work that is only possible by the advancement in sequencing technologies. Discovery of molecular markers is directly related to the NGS techniques and the role of markers in the phylogenetic and evolutionary studies is well known. For good quality of phylogeny as well as evolutionary studies, ecologists and evolutionary biologists need data from large numbers of individuals. These studies along with the power of NGS technology have been reported in many non-model organisms for determining the gene flow, population divergence, diversity level at intra- or inter-population, phylogeography, domestication process, and phylogenetic and evolutionary analyses (Grover *et al.*, 2012).

Conclusion and future prospects of next-generation sequencing

Next-generation sequencing technologies have revolutionized the field of plant genomics. As of today, the large chunk of this success is largely attributed to the second-generation sequencing tools. The areas which were significantly influenced by NGS technologies include genome sequencing, captured sequencing, exome sequencing, metagenomics, and plant transcriptomics; which includes mRNAs and non-coding RNAs and molecular markers and plant breeding. The continuous improvements in the field of sequencing technologies and associated decrease in sequencing costs has opened the door to small laboratories to take up plant genome sequencing projects. In spite of these developments, still there are considerable challenges in sequencing more complex genomes such as cross-pollinated crops and crop with higher polyploids. Nevertheless, researchers have taken interest in sequencing particular genomic regions and exomes, called as captured sequencing. This approach has considerably advanced our knowledge of those crops for which there is no sequence information available or which are only partially sequenced. NGS also has a significant role in metagenomics and enhanced the rate of analysis, especially in those circumstances where it would have been difficult to analyse using traditional tools and approaches. NGS-based transcriptome analysis has contributed significantly in transcriptome profiling of those plant species where no sequence information is available and also improve their ability to immensely contribute for novel genes to plant biology. NGS is playing a vital role in development of high throughput molecular markers as well.

However, the benefits of developments in the field of NGS tools can only be harvested by integrating the different genomics and genetics technologies and also advancements in biometrics and bioinformatics tools and techniques. This is going to be a challenging task in coming years. Finally, though captured sequencing has gained importance in past few years, largely due to sequencing costs and complexity involved in it, the future holds bright for whole genome sequencing, as the cost of sequencing is expected to decrease further and also the developments in the third-generation sequencing techniques have the potential to decrease the complexity by easily assembling of more complex genomes.
